Vigilance is the motto for the American Society of Anesthesiologists. Vigilance over the sedated pediatric dental patient is essential for safe and successful treatment. Especially important is vigilance over the patient’s airway.

If airway compromise can be quickly detected and corrected, then the likelihood of the patient experiencing a decrease in oxygen saturation will be low. Hypoxia caused by airway obstruction is a challenge faced by every pediatric dentist who chooses sedation as an alternative mode of treatment. Airway obstruction may be caused by several factors: poor patient positioning, blockage of the oropharynx by the tongue, fluids accumulating in the back of the throat, excess secretions, or collapse of soft tissues due to decreased muscle tone. These factors can lead to laryngospasm or bronchospasm, thus further compromising the airway.

While it has been reported that some pediatric dentists and pediatric dentistry training programs have decreased their use of sedation, many practitioners still view the use of sedative agents as acceptable treatment for the pre-cooperative child. The pediatric dentist today has an array of monitoring devices to protect the sedated patient. These monitors have been reviewed and discussed in great detail in the literature. Pulse oximeters and capnographs are two electronic monitors that have been described as the “favorites.” While these devices have brought many advances to the dental and medical fields, they are not without their limitations, especially when dealing with pediatric dental sedations (Table 1).

AAPD Guidelines for the Elective Use of Conscious Sedation, Deep Sedation and General Anesthesia in Pediatric Dental Patients (revised May, 1998), requires that patients be monitored continuously for patient responsiveness and airway patency. One of the most useful devices in the armamentarium of the pediatric dentist for continuous monitoring of the airway is the pretracheal/precordial stethoscope.

The use of the stethoscope in the monitoring of the anesthetized patient can be traced back to Cushing in 1909. The pretracheal/precordial stethoscope is a simple, yet highly effective device for the monitoring of respiratory and cardiac sounds. Traditionally, the device was comprised of an earpiece (universal or custom) which was connected to a weighted chestpiece through rubber or plastic tubing. The conventional stethoscopes operated on the basis of acoustic transmission, with the chestpiece placed above the patient’s sternal notch. AAPD Guidelines also state that “a pretracheal stethoscope shall be used for obtaining additional information on heart and respiratory rates and for monitoring airway patency during Level 3 sedations.”

The use and effectiveness of the pretracheal/precordial stethoscope has received mixed reviews in the literature. It has even been observed that one trend among anesthesiology trainees and providers is to replace (rather than supplement) pulse oximetry and capnography with the pretracheal/precordial stethoscope.
Although much of the criticisms about the limitations of the pretracheal/precordial stethoscope stem from the medical field and usually involve general anesthesia and the operating room, where more sophisticated monitors are usually available,11,12,14,15 it is the authors’ opinion that the pretracheal/precordial stethoscope can play a vital role in the safe and efficacious use of sedative agents in the pediatric dental setting.

The stethoscope’s ability to detect causes of airway obstruction makes it the first line of defense against potential disaster. It also gives the practitioner a more sensitive measure of the quality of the airway. As one author states: the anesthesiologist is still the most important monitor in the operating room and the choice of monitors should extend his or her senses. This is the most appropriate route to safe patient management.16

While pulse oximeters and capnographs give quantitative data; the stethoscope gives the clinician a plethora of qualitative information that can help diagnose potential risks (Table 2).

Like the pulse oximeter and the capnograph, the pretracheal/precordial stethoscope also has its limitations. It has been described how the traditional stethoscope “physically tethers the anesthetist to the patient.”15 One author explained how the traditional earpiece is quite uncomfortable and how only one listener can use the device at a time.17

Electronic wireless stethoscopes were developed to overcome some of these limitations and have been available to anesthesiologists for some time but carry a hefty price, approximately $900.15

Several have described different variations of the traditional pretracheal/precordial stethoscope and tested them in the medical arena (operating room/general anesthesia),10,11,15,17,18,19 but none have been described in the dental literature. We describe a wireless version of the traditional stethoscope and demonstrate how easy and economical it is to fabricate.

This version of the wireless pretracheal/precordial stethoscope functions on the basis of radio-wave transmission. It allows for more than one practitioner to listen at a time (teaching purposes), permits the practitioner to freely move around without being “tethered” to the patient, and provides clearer breath and heart sounds at a higher volume. The device will cost approximately $80 to make and takes about 15 minutes to put together. The necessary parts are shown in Figure 1 and listed in Table 3.

The wireless pretracheal/precordial stethoscope is an extension of the anesthetist’s senses, allowing close and continuous contact with the patient. It grants the anesthetist the ability to be more “vigilant” with auditory senses, thus protecting the patient’s safety.

### Instructions (Fig 2-5)
1. Insert Wenger chestpiece into Luer adapter.
2. Insert Luer adapter into one end of rubber tubing.
3. Insert transmitter microphone into the other end of the rubber tubing.

</tbody>
</table>

*Can be replaced with any FM wireless microphone system.
4. The 3M double-sided sticker is placed on the Wenger chestpiece and the chestpiece is placed above the patient’s sternal notch.
5. The receiver’s earpiece is placed in the listener’s ear.
