Abstract

The clinical features of a 7-year-old girl with enamel hypoplasia secondary to autoimmune hypoparathyroidism and chronic mucocutaneous candidiasis are detailed. The combination of features are typical of a rare, probably genetically determined immunodeficiency termed candidiasis endocrinopathy syndrome (CES). Affected individuals have chronic mucocutaneous candidiasis and a spectrum of autoimmune endocrinopathies, including hypoparathyroidism, adrenocortical hypofunction, and diabetes mellitus. Treatment includes long-term management of the candidal infection and correction of any associated endocrinopathy. (Pediatr Dent 17:216-19, 1995)

Candidiasis endocrinopathy syndrome (CES) is a rare, probably genetically determined immunodeficiency disorder characterized by recurrent and chronic candidal infections of the skin and mucosae (typically presenting in early childhood), and type 1 autoimmune polyendocrinopathy, usually hypoparathyroidism and/or hypoadrenocorticism. There are few reports of this disorder in the pediatric dental literature.

This report details the clinical features of a child whose main clinical feature was enamel hypoplasia due to hypoparathyroidism associated with CES.

Case report

A 7-year-old girl was referred for treatment of enlarged, nonpainful maxillary anterior gingivae, which had been present for several months. There was no associated gingival bleeding or pain.

There was a vague history of intermittent cramp-like pain in the thighs, unrelated to exercise or time of day. Of note, the patient had experienced episodes of oral pseudomembranous candidiasis and angular stomatitis that responded to short courses of topical nystatin and/or miconazole gel. The child had mild asthma for which she regularly used a beta-adrenergic inhaler. She had received immunizations against diphtheria, tetanus, pertussis, and poliomyelitis with no untoward reactions. The parents and two younger sisters all were healthy.

Extraoral examination revealed a painless granulomatous lesion of the right thumb nail (Fig 1) that had been present for at least 6 months. The other fingernails were normal, but several toenails were brittle and shortened. There were no oral mucosal anomalies, but the maxillary labial gingivae were slightly enlarged due to mild gingivitis.

Enamel hypoplasia affected the crowns of the right and left maxillary central and lateral incisors and both mandibular central incisors (Fig 2), but there was no hypoplasia of the first permanent molars or the primary teeth.
Fig 3. Hypoplasia affecting crowns of developing permanent canines and premolars.

Radiographs indicated horizontal ridging of the crowns of the maxillary right and left central and lateral incisors and enamel hypoplasia of the unerupted permanent canines (Fig 3).

In view of the previous history of intermittent oral candidiasis and probable candidal granuloma of the thumb nail, a provisional diagnosis of chronic mucocutaneous candidiasis (CMC) was made. The enamel hypoplasia suggested that there might also be associated hypoparathyroidism and therefore, CES.

The diagnosis was confirmed by hematological and serological investigations, which indicated that the child was hypocalcemic and hyperphosphatemic. The hypocalcemia was found to be secondary to hypoparathyroidism as shown by the almost undetectable levels of parathyroid hormone (Table 1). There was no evidence of hypoadrenocorticism or any other endocrine disorder. The child did not have autoantibodies to parietal cells, mitochondria, smooth muscle, or reticulin and hence was unlikely to have autoimmune hepatic disease, coeliac disease, or pernicious anemia. Vitamin D supplements were prescribed to correct the hypocalcemia, and the child was referred to a pediatric dentist who is currently advocating an intensive program of preventive measures to minimize any dental caries or gingivitis.

**Discussion**

Mucocutaneous candidiasis can give rise to a variety of clinical problems that include thrush (pseudomembranous candidiasis), median rhomboid glossitis, chronic atrophic candidiasis (denture-sore mouth), chronic hyperplastic candidiasis, and angular stomatitis. Oral candidiasis almost always reflects immunosuppression, tobacco smoking, xerostomia, or use of broad-spectrum antibiotics. CMC is the most rare and severe chronic candidal infection, characterized by recurrent and chronic disease of the skin and mucosae. In CMC the candidal infection typically affects the mouth and much less frequently the genitalia, conjunctivae, and other mucosae. Candidal infection of the nail bed gives rise to dystrophic nail changes and skin infection, which manifests as wart-like granulomas. CMC either can occur in isolation or in association with a variety of other systemic disorders (Table 2).

CES, also sometimes termed autoimmune polyendocrinopathy candidiasis-ectodermal dystrophy (APECED) or autoimmune polyglandular disease (type 1), is probably the most common variant of CMC and can arise spontaneously or may have an autosomal recessive mode of inheritance. Girls are affected more frequently than boys.

Pediatric Dentistry - 17:3, 1995

American Academy of Pediatric Dentistry 217
Candidal infection of the mouth manifesting as recurrent thrush and chronic hyperplastic candidiasis is often the initial presenting feature and clinical features of any associated endocrinopathy may not manifest for 10–15 years; occasionally, however, the sequence is reversed. There is no evidence that candidiasis is due to the endocrine anomalies, or vice versa.\textsuperscript{5,7}

Hypoparathyroidism is the endocrinopathy most commonly associated with CES but addisonian adrenocortical hypofunction, autoimmune thyroid disease, vitiligo, diabetes mellitus, and other autoimmune disorders also can arise.\textsuperscript{4,6,8}

The immunodeficiency in CES particularly involves defective T-cell function, but neutrophil and monocyte function also can be impaired. However, not all affected patients have defined immune defects, and individuals with similar immunodeficiencies do not all develop chronic candidal infection.\textsuperscript{1,2,9}

Oral features of CES include pseudomembranous candidiasis and recurrent angular stomatitis. Enamel hypoplasia may be seen secondary to hypoparathyroidism, usually affecting the permanent dentition, reflecting the early postnatal onset of the autoimmune hypoparathyroidism.\textsuperscript{10–14}

CES management requires antifungal therapy and treatment of the endocrinopathy. Candidal infection of the mouth usually is responsive to topical antifungal therapy, particularly with nystatin or amphotericin B. However, in CMC the infection can be recalcitrant to such measures, hence systemic antifungals such as fluconazole or ketoconazole often are required.\textsuperscript{1–14} Correction of the endocrinopathy usually requires replacement of any absent hormones. Hypoparathyroidism requires vitamin D analogue therapy to maximize gut absorption of calcium and, calcium supplements also may be required.\textsuperscript{14}

In summary, the oral features of a child with CES have been detailed. The young girl presented with enamel hypoplasia, a history of previous oral candidiasis and subsequently was found to have CES, the enamel hypoplasia due to accompanying hypoparathyroidism. Because of its rarity, CES probably represents one of the less likely primary immunodeficiency disorders to give rise to oral manifestations.
