Purpose
The American Academy of Pediatric Dentistry (AAPD) recognizes the importance of managing the developing dentition and occlusion and its effect on the well-being of infants, children, and adolescents. Management includes the recognition, diagnosis, and appropriate treatment of dentofacial abnormalities. This guideline is intended to set forth objectives for management of the developing dentition and occlusion in pediatric dentistry.

Methods
This revision is based upon a new MEDLINE search using the following parameters: Terms: ankylosis, anterior crossbite, Class II malocclusion, Class III malocclusion, dental crowding, ectopic eruption, impaction, obstruction sleep apnea syndrome (OSAS), occlusal development, oligodontia, oral habits, posterior crossbite, space maintenance, and tooth size/arch length discrepancy; Field: all fields; Limits: within the last 10 years, humans, English, and birth through age 18. Papers for review were chosen from this search and from references within selected articles. When data did not appear sufficient or were inconclusive, recommendations were based upon expert and/or consensus opinion by experienced researchers and clinicians.

Background
Guidance of eruption and development of the primary, mixed, and permanent dentitions is an integral component of comprehensive oral health care for all pediatric dental patients. Such guidance should contribute to the development of a permanent dentition that is in a stable, functional, and esthetically acceptable occlusion. Early diagnosis and successful treatment of developing malocclusions can have both short-term and long-term benefits while achieving the goals of occlusal harmony and function and dentofacial esthetics. Many factors can affect the management of the developing dental arches and minimize the overall success of any treatment. The variables associated with the treatment of the developing dentition that will affect the degree to which treatment is successful include, but are not limited to:
1. chronological/mental/emotional age of the patient and the patient’s ability to understand and cooperate in the treatment;
2. intensity, frequency, and duration of an oral habit;
3. parental support for the treatment;
4. compliance with clinician’s instructions;
5. craniofacial configuration;
6. craniofacial growth;
7. concomitant systemic disease or condition;
8. accuracy of diagnosis;
A thorough clinical examination, appropriate pretreatment records, differential diagnosis, sequential treatment plan, and progress records are necessary to manage any condition affecting the developing dentition.
Clinical examination should include:
1. facial analysis to:
   a. identify adverse transverse growth patterns including asymmetries (maxillary and mandibular);
   b. identify adverse vertical growth patterns;
   c. identify adverse sagittal (anteroposterior) growth patterns and dental anteroposterior (AP) occlusal disharmonies;
   d. assess esthetics and identify orthopedic and orthodontic interventions that may improve esthetics and resultant self-image and emotional development.
2. intraoral examination to:
   a. assess overall oral health status;
   b. determine the functional status of the patient’s occlusion.
3. functional analysis to:
   a. determine functional factors associated with the malocclusion;
b. detect deleterious habits;
c. detect temporomandibular joint dysfunction, which may require additional diagnostic procedures.

Diagnostic records may be needed to assist in the evaluation of the patient's condition and for documentation purposes. Prudent judgment is exercised to decide the appropriate records required for diagnosis of the clinical condition.6

Diagnostic orthodontic records fall into 3 major categories of evaluation: (1) health of the teeth and oral structures, (2) alignment and occlusal relationships of the teeth, and (3) facial and jaw proportions which includes both cephalometric radiographs and facial photographs. Digital images rapidly are replacing film, but both are acceptable as records.6

Diagnostic records may include:
1. extraoral and intraoral photographs to:
   a. supplement clinical findings with oriented facial and intraoral photographs;
   b. establish a database for documenting facial changes during treatment.
2. diagnostic dental casts to:
   a. assess the occlusal relationship;
   b. determine arch length requirements for intraarch tooth size relationships;
   c. determine arch length requirements for interarch tooth size relationships;
   d. determine location and extent of arch asymmetry.
3. intraoral and panoramic radiographs to:
   a. establish dental age;
   b. assess eruption problems;
   c. estimate the size and presence of unerupted teeth;
   d. identify dental anomalies/pathology.
4. lateral and AP cephalograms to:
   a. produce a comprehensive cephalometric analysis of the relative dental and skeletal components in the anteroposterior, vertical, and transverse dimensions;
   b. establish a baseline growth record for longitudinal assessment of growth and displacement of the jaws.
5. other diagnostic views (eg, magnetic resonance imaging, computed tomographic scans) for hard and soft tissue imaging as indicated by history and clinical examination.

A differential diagnosis and diagnostic summary are completed to:
1. establish the relative contributions of the dental and skeletal structures to the patient’s malocclusion;
2. prioritize problems in terms of relative severity;
3. detect favorable and unfavorable interactions that may result from treatment options for each problem area;
4. establish short-term and long-term objectives;
5. summarize the prognosis of treatment for achieving stability, function, and esthetics.

A sequential treatment plan will:
1. establish timing priorities for each phase of therapy;
2. establish proper sequence of treatments to achieve short-term and long-term objectives;
3. assess treatment progress and update the biomechanical protocol accordingly on a regular basis.

**Stages of development of occlusion**

**General considerations and principles of management:** The stages of occlusal development include:

1. Primary dentition: Beginning in infancy with the eruption of the first tooth, usually about 6 months of age, and complete from approximately 3 to 6 years of age when all primary teeth are erupted.
2. Mixed dentition: From approximately age 6 to 13, primary and permanent teeth are present in the mouth.
3. Adolescent dentition: All primary teeth have exfoliated, second permanent molars may be erupted or erupting, and third molars have not erupted.
4. Adult dentition: All permanent teeth are present and eruptive growth is complete.7-10

These stages may further be divided and referenced as “early” and “late” (eg, early primary, late primary, early mixed, late mixed).7-10

Evaluation and treatment of occlusal and skeletal disharmonies may be initiated at various stages of dental arch development, depending on the problems, growth, parental involvement, risks and benefits of treatment and of withholding treatment, and interest/ability of the practitioner.5

Historically, orthodontic treatment was provided mainly for adolescents. Interest continues to be expressed in early treatment as well as in adult treatment. Treatment and timing options for the growing patient, especially in the mixed dentition and early permanent dentition, have increased and continue to be evaluated by the research community.9,11-13 Many clinicians seek to modify skeletal, muscular, and dentoalveolar abnormalities before the eruption of the full permanent dentition.7

A thorough knowledge of craniofacial growth and development of the dentition, as well as orthodontic treatment, must be used in diagnosing and reviewing possible treatment options before recommendations are made to parents.7 Early treatment is beneficial for many children but may not be indicated for every patient.

**Treatment considerations:** The developing dentition should be monitored throughout eruption. This monitoring at regular clinical examinations should include, but not be limited to, diagnosis of missing, supernumerary, developmentally defective, and fused or geminated teeth; ectopic eruption; and space and tooth loss secondary to caries.

Radiographic examination, when appropriate14 and feasible, should accompany clinical examination. Diagnosis of anomalies of primary or permanent tooth development and eruption should be made to inform the patient’s parent and to plan and recommend appropriate intervention. This evaluation is ongoing throughout the developing dentition, at all stages.6-10
1. Primary dentition stage: Anomalies of primary teeth and eruption may not be evident/diagnosable prior to eruption, due to the child’s not presenting for dental examination or to a radiographic examination not being possible in a young child. Evaluation, however, should be accomplished when feasible. The objectives of evaluation include identification of:
   a. all anomalies of tooth number and size (as previously noted);
   b. anterior and posterior crossbites;
   c. presence of habits along with their dental and skeletal sequelae.
Radiographs are taken with appropriate clinical indicators or based upon risk assessment/history.

2. Early mixed dentition stage: Palpation for unerupted teeth should be part of every examination. Panoramic, occlusal, and periapical radiographs, as indicated at the time of eruption of the lower incisors and first permanent molars, provide diagnostic information concerning:
   a. anomalies of tooth numbers (eg, missing, supernumerary, fused, gminated);
   b. tooth size and shape (eg, peg or small lateral incisors);
   c. positions (eg, ectopic first permanent molars).
Space analysis can be used to evaluate arch length/crowding at the time of incisor eruption.

3. Mid-to-late mixed dentition stage: Ectopic tooth positions should be diagnosed, especially canines, bicuspids, and second permanent molars.

4. Adolescent dentition stage: If not instituted earlier, orthodontic diagnosis and treatment should be planned for Class I crowded, Class II, and Class III malocclusions as well as posterior and anterior crossbites. Third molars should be monitored as to position and space, and parents should be informed.

5. Early adult dentition stage: Third molar positions should be evaluated. If orthodontic diagnosis has not been accomplished, recommendations should be made as necessary.

**Objectives:** At each stage, the objectives of intervention/treatment include reducing adverse growth, preventing increasing dental and skeletal disharmonies, improving esthetics of the smile and the accompanying positive effects on self-image, and improving the occlusion.

1. Primary dentition stage: Habits and posterior crossbites should be diagnosed and addressed as early as feasible. Parents should be informed about findings of adverse growth and developing malocclusions. Interventions/treatment can be recommended if diagnosis can be made, treatment is appropriate and possible, and parents are supportive and desire to have treatment done.

2. Early mixed stage: Treatment should address: (1) habits; (2) arch length shortage; (3) intervention for crowded incisors; (4) intervention for ectopic molars and incisors; (5) holding of leeway space; (6) crossbites; and (7) adverse skeletal growth. Treatment should take advantage of high rates of growth and prevent worsened adverse dental and skeletal growth.

3. Mid-to-late mixed dentition stage: Intervention for ectopic teeth may include extractions and space maintenance to aid eruption and reduce the risk of need for surgical bracket placement and orthodontic traction. Intervention for treatment of skeletal disharmonies and crowding may be instituted at this stage.

4. Adolescent dentition stage: In full permanent dentition, final orthodontic diagnosis and treatment can provide the most functional occlusion.

5. Early adult dentition stage: Third molar position or space can be evaluated and, if indicated, the tooth removed. Full orthodontic treatment should be recommended if needed.

**Recommendations**

**Oral habits**

General considerations and principles of management: The habits of nonnutritive sucking, bruxing, tongue thrust swallow and abnormal tongue position, self-injurious/self-mutilating behavior, and airway obstruction (OSAS) are discussed in this guideline.

Oral habits may apply forces to the teeth and dentoalveolar structures. The relationship between oral habits and unfavorable dental and facial development is associational rather than cause and effect.15-17 Habits of sufficient frequency, duration, and intensity may be associated with dentoalveolar or skeletal deformations such as increased overjet, reduced overbite, posterior crossbite, or long facial height. The duration of force is more important than its magnitude; the resting pressure from the lips, cheeks, and tongue has the greatest impact on tooth position, as these forces are maintained most of the time.18,19

Nonnutritive sucking behaviors are considered normal in infants and young children. Prolonged nonnutritive sucking habits have been associated with decreased maxillary arch width, increased overjet, decreased overbite, anterior open bite, and posterior crossbite.16,18,19 As preliminary evidence indicates that some changes resulting from sucking habits persist past the cessation of the habit, it has been suggested that early dental visits provide parents with anticipatory guidance to help their children stop sucking habits by age 36 months or younger.16,18,19

Bruxism, defined as the habitual nonfunctional and forceful contact between occlusal surfaces, can occur while awake or asleep. The etiology is multifactorial and has been reported to include central factors (eg, emotional stress,20 parasomnias,21 traumatic brain injury,22 neurologic disabilities23) and morphologic factors (eg, malocclusion24, muscle recruitment25). Reported complications include dental attrition, headaches, temporomandibular dysfunction, and soreness of the masticatory muscles.26 Preliminary evidence suggests that juvenile
bruxism is a self-limiting condition that does not progress to adult bruxism. The spectrum of bruxism management ranges from patient/parent education, occlusal splints, and psychological techniques to medications.

Tongue thrusting, an abnormal tongue position and deviation from the normal swallowing pattern, may be associated with anterior open bite, abnormal speech, and anterior protrusion of the maxillary incisors. There is no evidence that intermittent short-duration pressures, created when the tongue and lips contact the teeth during swallowing or chewing, have significant impact on tooth position. If the resting tongue posture is forward of the normal position, incisor displacement is likely, but if resting tongue posture is normal, a tongue thrust swallow has no clinical significance.

Self-injurious or self-mutilating behavior (ie, repetitive acts that result in physical damage to the individual) is extremely rare in the normal child. Such behavior, however, has been associated with mental retardation, psychiatric disorders, developmental disabilities, and some syndromes. The spectrum of treatment options for developmentally disabled individuals includes pharmacologic management, behavior modification, and physical restraint. Reported dental treatment modalities include, among others, lip-bumper and occlusal bite appliances, protective pad-ting, and extractions. Some habits, such as lip-licking and lip-pulling, are relatively benign in relation to an effect on the dentition. More severe lip- and tongue-biting habits may be associated with profound neurodisability due to severe brain damage.

Management options include monitoring the lesion, odontoplasty, providing a bite-opening appliance, or extracting the teeth.

Research on the relationship between malocclusion and mouth breathing suggests that impaired nasal respiration may contribute to the development of increased facial height, anterior open bite, increased overjet, and narrow palate, but it is not the sole or even the major cause of these conditions.

OSAS may be associated with narrow maxilla, crossbite, low tongue position, vertical growth, and open bite. History associated with OSAS may include snoring, observed apnea, restless sleep, daytime neurobehavioral abnormalities or sleepiness, and bedwetting. Physical findings may include growth abnormalities, signs of nasal obstruction, adenoidal facies, and/or enlarged tonsils.

The identification of an abnormal habit and the assessment of its potential immediate and long-term effects on the craniofacial complex and dentition should be made as early as possible. The dentist should evaluate habit frequency, duration, and intensity in all patients with habits. Intervention to terminate the habit should be initiated if indicated.

Patients and their parents should be provided with information regarding consequences of a habit. Parents may play a negative role in the correction of an oral habit as nagging or punishment may result in an increase in habit behaviors; change in the home environment may be necessary before a habit can be overcome.

Treatment considerations: Management of an oral habit is indicated whenever the habit is associated with unfavorable dentofacial development or adverse effects on child health or when there is a reasonable indication that the oral habit will result in unfavorable sequelae in the developing permanent dentition. Any treatment must be appropriate for the child’s development, comprehension, and ability to cooperate. Habit treatment modalities include patient/parent counseling, behavior modification techniques, myofunctional therapy, appliance therapy, or referral to other providers including, but not limited to, orthodontists, psychologists, myofunctional therapists, or otolaryngologists. Use of an appliance to manage oral habits is indicated only when the child wants to stop the habit and would benefit from a reminder.

Objectives: Treatment is directed toward decreasing or eliminating the habit and minimizing potential deleterious effects on the dentofacial complex.

Disturbances in number
Congenitally missing teeth

General considerations and principles of management: Hypodontia, the congenital absence of 1 or more permanent teeth, has a prevalence of 3.5% to 6.5%. Excluding third molars, the most frequently missing permanent tooth is the mandibular second premolar followed by the maxillary lateral incisor. In the primary dentition, hypodontia occurs less (0.1% to 0.9% prevalence) and almost always affects the maxillary incisors and first primary molars. The chance of familial occurrence of 1 or 2 congenitally missing teeth is to be differentiated from missing lateral incisors in cleft lip/palate and multiple missing teeth (6 or more) due to ectodermal dysplasia or other syndromes as the treatment usually differs. A congenitally missing tooth should be suspected in patients with cleft lip/palate, certain syndromes, and a familial pattern of missing teeth. In addition, patients with asymmetric eruption sequence or ankylosis of a primary mandibular second molar may have a congenitally missing tooth.

Treatment considerations: With congenitally missing permanent maxillary incisor(s) or mandibular second premolar(s), the decision to extract the primary tooth and close the space orthodontically versus opening the space orthodontically and placing a prosthesis or implant depends on many factors. For maxillary laterals, the dentist may move the maxillary canine mesially and use the canine as a lateral incisor or create space for a future lateral prosthesis or implant.

Factors that influence the decision are: (1) patient age; (2) canine shape; (3) canine position; (4) child’s occlusion and amount of crowding; (5) bite depth; and (6) quality and quantity of bone in the edentulous area. Early extraction of the primary canine and/or lateral may be needed. Opening space for a prosthesis or implant requires less tooth movement, but the space needs to be maintained with an interim prosthesis, especially if an implant is planned. Moving the canine into the lateral position produces little facial change, but the resultant tooth size discrepancy often does not allow a canine guided occlusion.
For a congenitally missing premolar, the primary molar either may be maintained or extracted with subsequent placement of a prosthesis or orthodontically closing the space. Maintaining the primary second molar may cause occlusal problems due to its larger mesiodistal diameter, compared to the second premolar. Reducing the width of the second primary molar is a consideration, but root resorption and subsequent exfoliation may occur. In crowded arches or with multiple missing premolars, extraction of the primary molar(s) can be considered, especially in mild Class III cases. For a single missing premolar, if maintaining the primary molar is not possible, placement of a prosthesis or implant should be considered. Consultation with an orthodontist and/or prosthodontist may be required. In addition, preserving the primary tooth may be indicated in certain cases.

Objectives: Treatment is directed toward an esthetically pleasing occlusion that functions well for the patient.

Supernumerary teeth (primary, permanent, and mesiodens)

General considerations and principles of management: Supernumerary teeth, or hyperdontia, can occur in the primary or permanent dentition but are 5 times more common in the permanent. Prevalence is reported in the primary and mixed dentitions from 0.52% to 2%. Between 80% and 90% of all supernumerary teeth occur in the maxilla, with half in the anterior area and almost all in the palatal position. A supernumerary primary tooth is followed by a supernumerary permanent tooth in one third of the cases.

During the early mixed dentition, 79% to 91% of anterior permanent supernumerary teeth are unerupted. While more erupt with age, only 25% of all mesiodens (a permanent supernumerary incisor located at the midline) erupt spontaneously. Mesiodens can prevent or cause ectopic eruption of a central incisor. Less frequently, a mesiodens can cause dilaceration or resorption of the permanent incisor’s root. Dentigerous cyst formation involving the mesiodens, in addition to eruption into the nasal cavity, has been reported.

If there is an asymmetric eruption pattern of the maxillary incisors, with pulpally-treated primary incisors, with asymmetric eruption of an incisor, a supernumerary can be suspected. Panoramic, occlusal, and periapical radiographs all can reveal a supernumerary, but the best way to locate the supernumerary is 2 periapical or occlusal films reviewed by the parallax rule.

Treatment considerations: Management and treatment of hyperdontia differs if the tooth is primary or permanent. Primary supernumerary teeth normally are accommodated into the arch and usually erupt and exfoliate without complications. Extraction of an unerupted supernumerary tooth during the primary dentition usually is not done to allow it to erupt; surgical extraction of unerupted supernumerary teeth can displace or damage the permanent incisor. Removal of a mesiodens or other permanent supernumerary incisor results in eruption of the permanent adjacent normal incisor in 75% of the cases. Extraction of an unerupted supernumerary during the early mixed dentition allows for a normal eruptive force and eruption of the permanent adjacent normal incisor. Later removal of the mesiodens reduces the likelihood that the adjacent normal permanent incisor will erupt on its own, especially if the apex is completed. Inverted conical supernumeraries can be harder to remove if removal is delayed, as they can migrate deeper into the jaw. After removal of the supernumery, clinical and radiographic follow-up is indicated in 6 months to determine if the normal incisor is erupting. If there is no eruption after 6 to 12 months and sufficient space exists, surgical exposure and orthodontic extrusion is needed.

Objectives: Removal of supernumerary teeth should facilitate eruption of permanent teeth and encourage normal alignment. In cases where normal alignment or spontaneous eruption does not occur, further orthodontic treatment is indicated.

Localized disturbances in eruption

Ectopic eruption

General considerations and principles of management: Ectopic eruption (EE) of permanent first molars occurs due to the molar’s abnormal mesioangular eruption path, resulting in an impaction at the distal prominence of the primary second molar’s crown. EE can be suspected if asymmetric eruption is observed or if the mesial marginal ridge is noted to be under the distal prominence of the second primary molar. EE of permanent molars can be diagnosed from bitewing or panoramic radiographs in the early mixed dentition. This condition occurs in up to 0.75% of the population, but is more common in children with cleft lip and palate.

The maxillary canine appears in an impacted position in 1.5% to 2% of the population, while maxillary incisors can erupt ectopically or be impacted from supernumerary teeth in up to 2% of the population. Incisors also can have altered eruption due to pulp necrosis (following trauma or caries) or pulpal treatment of the primary incisor.

EE of permanent molars is classified into 2 types. There are those that self correct or “jump” and others that remain impacted. In 66% of the cases, the molar jumps. A permanent molar that presents with part of its occlusal surface clinically visible and part under the distal of the primary second molar normally does not jump and is the impacted type. Nontreatment can result in early loss of the primary second molar and space loss.

Maxillary canine impaction should be suspected when the canine bulge is not palpable or when asymmetric canine eruption is evident. Panoramic radiographs would show the canine has an abnormal inclination and/or overlaps the lateral incisor root. EE of permanent incisors can be suspected after trauma to primary incisors, with pulpally-treated primary incisors, with asymmetric eruption, or if a supernumerary incisor is diagnosed.

Treatment considerations: Treatment depends on how severe the impaction appears clinically and radiographically. For mildly impacted first permanent molars, where little of the tooth is impacted under the primary second molar, elastic or metal orthodontic separators can be placed to wedge the permanent first molar distally. For more severe impactions, distal tipping of the permanent molar is required. Tipping action can be accomplished with brass wires, removable appliances using...
springs, fixed appliances such as sectional wires with open coil springs, sling-shot-type appliances,\textsuperscript{60} a Halterman appliance,\textsuperscript{61} or surgical uprighting.\textsuperscript{62}

Early diagnosis and treatment of impacted maxillary canines can lessen the severity of the impaction and may stimulate eruption of the canine. Extraction of the primary canine is indicated when the canine bulge cannot be palpated in the alveolar process and there is radiographic overlapping of the canine with the formed root of the lateral during the mixed dentition.\textsuperscript{63} Even when the impacted canine is diagnosed at a later age (11 to 16), if the canine is not horizontal, extraction of the primary canine lessens the severity of the permanent canine impaction and 75\% will erupt.\textsuperscript{64} Extraction of the first primary molar also has been reported to allow eruption of first bicuspid and to assist in the eruption of the cuspsids. This need can be determined from a panoramic radiograph.\textsuperscript{61,65} Bonded orthodontic treatment normally is required to create space or align the canine. Long-term periodontal health of impacted canines after orthodontic treatment is similar to nonimpacted canines.\textsuperscript{68}

Treatment of ectopically erupting incisors depends on the etiology. Extraction of necrotic or over-retained pulparly-treated primary incisors is indicated in the early mixed dentition.\textsuperscript{58} Removal of supernumerary incisors in the early mixed dentition will lessen ectopic eruption of an adjacent permanent incisor.\textsuperscript{67} After incisor eruption, orthodontic treatment involving removable or banded therapy may be needed.

Objectives: Management of ectopically erupting molars, canines, and incisors should result in improved eruptive positioning of the tooth. In cases where normal alignment does not occur, subsequent comprehensive orthodontic treatment may be necessary to achieve appropriate arch form and intercuspal.

\textbf{Ankylosis}

\textbf{General considerations and principles of management:} Ankylosis is a condition in which the cementum of a tooth's root fuses directly to the surrounding bone. The periodontal ligament is replaced with osseous tissue, rendering the tooth immobile to eruptive change. Ankylosis can occur in the primary and permanent dentitions, with the most common incidence involving primary molars. The incidence is reported to be between 7\% and 14\% in the primary dentition. In the permanent dentition, ankylosis occurs most frequently following luxation injuries.\textsuperscript{67}

Ankylosis is common in anterior teeth following trauma and is referred to as replacement resorption. Periodontal ligament cells are destroyed and the cells of the alveolar bone perform most of the healing. Over time, normal bony activity results in the replacement of root structure with osseous tissue.\textsuperscript{67} Ankylosis can occur rapidly or gradually over time, in some cases as long as 5 years post trauma. It also may be transient if only a small bony bridge forms that can be resorbed with subsequent osteoclastic activity.\textsuperscript{69}

Ankylosis can be verified by clinical and radiographic means. Submergence of the tooth is the primary recognizable sign, but the diagnosis also can be made through percussion and palpation. Radiographic examination also may reveal the loss of the periodontal ligament and bony bridging.

\textbf{Treatment considerations:} With ankylosis of a primary molar, exfoliation usually occurs normally. Extraction is recommended if prolonged retention of the primary molar is noted. If a severe marginal ridge discrepancy develops, extraction should be considered to prevent the adjacent teeth from tipping and producing space loss.\textsuperscript{3} Replacement resorption of permanent teeth usually results in the loss of the involved tooth.\textsuperscript{57}

Mildly to moderately ankylosed primary molars without permanent successors may be retained and restored to function in arches without crowding. Extraction of these molars can assist in resolving crowded arches in complex orthodontic cases.\textsuperscript{65,70} Surgical luxation of ankylosed permanent teeth with forced eruption has been described as an alternative to premature extraction.\textsuperscript{71}

Objectives: Treatment of ankylosis should result in the continuing normal development of the permanent dentition. Or, in the case of replacement resorption of a permanent tooth, appropriate prosthetic replacement should be planned.

\textbf{Tooth size/arch length discrepancy and crowding}

\textbf{General considerations and principles of management:} Arch length discrepancies include inadequate arch length and crowding of the dental arches, excess arch length and spacing, and tooth size discrepancy, often referred to as a Bolton discrepancy.\textsuperscript{72} These arch length discrepancies may be found in conjunction with complicating and other etiological factors including missing teeth, supernumerary teeth, and fused or geminated teeth. Inadequate arch length with resulting incisor crowding is a common occurrence with various negative sequelae and is particularly common in the early mixed dentition.\textsuperscript{73-76} Studies of arch length in today's children compared to their parents and grandparents of 50 years ago indicate less arch length, more frequent incisor crowding, and stable tooth sizes.\textsuperscript{77} This implies that the problem of incisor crowding and ultimate arch length discrepancies may be increasing in numbers of patients and in amount of arch length shortage.\textsuperscript{77,78}

Arch length and especially crowding must be considered in the context of the esthetic, dental, skeletal, and soft tissue relationships. Mandibular incisors have a high relapse rate in rotations and crowding.\textsuperscript{73,75} Growth of the aging skeleton causes further crowding and incisor rotations.\textsuperscript{82} Functional contacts are diminished where rotations of incisors, canines, and bicuspid exist.\textsuperscript{83} Occlusal harmony and temporomandibular joint health are impacted negatively by less functional contacts.\textsuperscript{93}

Initial assessment may be done in early mixed dentition, when mandibular incisors begin to erupt.\textsuperscript{73} Evaluation of available space and consideration of making space for permanent incisors to erupt may be done initially utilizing appropriate radiographs to ascertain the presence of permanent successors. Comprehensive diagnostic analysis is suggested, with evaluation of maxillary and mandibular skeletal relationships, direc-
tion and pattern of growth, facial profile, facial width, muscle balance, and dental and occlusal findings including tooth positions, arch length analysis, and leeway space.

Derotation of teeth just after emergence in the mouth implies correction before the transseptal fiber arrangement has been established. It has been shown that the transseptal fibers do not develop until the cementoenamel junction of erupting teeth pass the bony border of the alveolar process. Long-term stability of aligned incisors may be increased.

Treatment considerations: Treatment considerations may include, but are not limited to:
1. making space for permanent incisors to erupt and become straight naturally through primary canine extraction and space/arch length maintenance;
2. orthodontic alignment of permanent teeth as soon as erupted and feasible, expansion and correction of arch length as early as feasible;
3. utilizing holding arches in the mixed dentition until all permanent bicuspids and canines have erupted;
4. extractions of permanent teeth;
5. maintaining patient’s original arch form.

Other treatment modalities may include, but are not limited to: (1) interproximal reduction; (2) restorative bonding; (3) veneers; (4) crowns; (5) implants; and (6) orthognathic surgery.

Objectives: Well-timed intervention can:
1. prevent crowded incisors;
2. increase long-term stability of incisor positions;
3. decrease ectopic eruption and impaction of permanent canines;
4. reduce orthodontic treatment time and sequelae;
5. improve gingival health and overall dental health.

Space maintenance
General considerations and principles of management: The premature loss of primary teeth due to caries, trauma, ectopic eruption, or other causes may lead to undesirable tooth movements of primary and/or permanent teeth including loss of arch length. Arch length deficiency can produce or increase the severity of malocclusions with crowding, rotations, ectopic eruption, crossbite, excessive overjet, excessive overbite, and unfavorable molar relationships. The dental profession has recommended the use of space maintainers to reduce the prevalence and severity of malocclusion following premature loss of primary teeth. Space maintenance may be a consideration in the primary dentition after early loss of a maxillary incisor when the child has an active digit habit. An intense habit may retard eruption of the permanent teeth due to caries, trauma, ectopic eruption, or other causes.

Adverse effects associated with space maintainers include: (1) dislodged, broken, and lost appliances; (2) plaque accumulation; (3) caries; (4) interference with successor eruption; (5) undesirable tooth movement; (6) inhibition of alveolar growth; (7) soft tissue impingement; and (8) pain. Premature loss of a primary tooth of any type has the potential to cause loss of space available for the succeeding permanent tooth, but there is a lack of consensus regarding the effectiveness of space maintainers in preventing or reducing the severity of malocclusion.

Treatment considerations: It is prudent to consider space maintenance when primary teeth are lost prematurely. Factors to consider include: (1) specific tooth lost; (2) time elapsed since tooth loss; (3) pre-existing occlusion; (4) favorable space analysis; (5) presence and root development of permanent successor; (6) amount of alveolar bone covering permanent successor; (7) patient’s health status; (8) patient’s cooperative ability; (9) active oral habits; and (10) oral hygiene. If a space analysis is required prior to the placement of a space maintainer, appropriate radiographs and study models should be considered.

The literature pertaining to the use of space maintainers specific to the loss of a particular primary tooth type include expert opinion, case reports, and details of appliance design. Treatment modalities may include, but are not limited to:
1. fixed appliances (eg, band and loop, crown and loop, passive lingual arch, distal shoe, Nance appliance, transpalatal arch);
2. removable appliances (eg, partial dentures, Hawley appliance).

The placement and retention of space maintaining appliances requires ongoing compliant patient behavior. Follow-up of patients with space maintainers is necessary to assess integrity of cement and to evaluate and clean the abutment teeth. The appliance should function until the succedaneous teeth have erupted into the arch.

Objectives: The goal of space maintenance is to prevent loss of arch length, width, and perimeter by maintaining the relative position of the existing dentition.

The AAPD supports controlled randomized clinical trials to determine efficacy of space maintainers as well as analysis of costs and side effects of treatment.

Space regaining
General considerations and principles of management: Some of the more common causes of space loss within an arch are (1) primary teeth with interproximal caries; (2) ectopically erupting teeth; (3) alteration in the sequence of eruption; (4) ankylosis of a primary molar; (5) dental impaction; (6) transposition of teeth; (7) loss of primary molars without proper space management; (8) congenitally missing teeth; (9) abnormal resorption of primary molar roots; (10) premature and delayed eruption of permanent teeth; and (11) abnormal dental morphology. Loss of space in the dental arch that interferes with the desired eruption of the permanent teeth may require evaluation.

Space loss may occur unilaterally or bilaterally and may result from teeth tipping, rotating, extruding, being anklosed, or translating or from extrusion of teeth and the deepening of the curve of Spee.

The degree to which space is affected varies according to the arch affected, site in the arch, and time elapsed since tooth loss. The quantity and incidence of space loss also are dependent upon which adjacent teeth are present in the dental arch.
and their status.\textsuperscript{17,87} The amount of crowding or spacing in the dental arch will determine the degree to which space loss has a significant consequence.\textsuperscript{1,98}

**Treatment considerations:** Treatment modalities may include, but are not limited to, fixed appliances or removable appliances (eg, Hawley appliance, lip bumper, headgear). Space loss and dentofacial skeletal development may dictate that space regaining not be indicated. This should be determined as the result of a comprehensive analysis. The timing of clinical intervention subsequent to premature loss of a primary molar is critical.\textsuperscript{1}

**Objectives:** The goal of space regaining intervention is the recovery of lost arch width and perimeter and/or improved eruptive position of succedaneous teeth. Space regained should be maintained until adjacent permanent teeth have erupted completely and/or until a subsequent comprehensive orthodontic treatment plan is initiated.

**Crossbites (dental, functional, and skeletal)**

**General considerations and principles of management:** Anterior and posterior crossbites are malocclusions which involve one or more teeth in which the maxillary teeth occlude lingually with the antagonistic mandibular teeth.\textsuperscript{99,100} If the midlines undergo a compensatory or habitual shift when the teeth occlude in crossbite, this is termed a functional shift.\textsuperscript{101} A crossbite can be of dental or skeletal origin or a combination of both.\textsuperscript{102}

A simple anterior crossbite is of dental origin if the molar occlusion is Class I and the malocclusion is the result of an abnormal axial inclination of maxillary anterior teeth. This condition should be differentiated from a Class III skeletal malocclusion where the crossbite is the result of the basal bone position.\textsuperscript{100} Dental crossbites result from the tipping or rotation of a tooth or teeth. The condition is localized and does not involve the basal bone. Skeletal crossbites involve disharmony of the craniofacial skeleton. Aberrations in bony growth may give rise to crossbites in 2 ways:

1. adverse transverse growth of the maxilla and mandible;
2. disharmonious or adverse growth in the sagittal (AP) length of the maxilla and mandible.\textsuperscript{99,101}

Such growth aberrations can be due to inherited growth patterns, trauma, or functional disturbances that alter normal growth.

**Treatment considerations:** Crossbites should be considered in the context of the patient’s total treatment needs. Anterior crossbite correction can: (1) reduce dental attrition; (2) improve dental esthetics; (3) redirect skeletal growth; (4) improve the tooth-to-alveolus relationship; and (5) increase arch perimeter. A simple anterior crossbite can be aligned as soon as the condition is noted, if there is sufficient space; otherwise, space needs to be created first. Such appliances as acrylic incline planes, acrylic retainers with lingual springs, or fixed appliances all have been effective. If space is needed, an expansion appliance also is required.\textsuperscript{99} Posterior crossbite correction can accomplish the same objectives and can improve the eruptive position of the succedaneous teeth. Early correction of unilateral posterior crossbites has been shown to improve functional conditions significantly and largely eliminate morphological and positional asymmetries of the mandible.\textsuperscript{103,104} Functional shifts should be eliminated as soon as possible with early correction to avoid asymmetric growth. Treatment can be completed with:

1. equilibration;
2. appliance therapy (fixed or removable);
3. extractions; or
4. a combination of these treatment modalities to correct the palatal constriction.

Fixed or removable palatal expanders can be utilized until midline suture fusion occurs.\textsuperscript{101,102} Treatment decisions depend on the:

1. amount and type of movement (tipping vs bodily movement, rotation, or dental vs orthopedic movement);
2. space available;
3. AP, transverse, and vertical skeletal relationships;
4. growth status;
5. patient cooperation.

Patients with crossbites and concomitant Class III skeletal patterns and/or skeletal asymmetry should receive comprehensive treatment as covered in the Class III malocclusion section.

**Objectives:** Treatment of a crossbite should result in improved intramaxillary alignment and an acceptable interarch occlusion and function.\textsuperscript{103}

**Class II malocclusion**

**General considerations and principles of management:** Class II malocclusion (distocclusion) may be unilateral or bilateral and involves a distal relationship of the mandible to the maxilla or the mandibular teeth to maxillary teeth. This relationship may result from dental (malposition of the teeth in the arches), skeletal (mandibular retrusion and/or maxillary protrusion), or a combination of dental and skeletal factors.\textsuperscript{6}

Results of randomized clinical trials indicate that Class II malocclusion can be corrected effectively with either a single or 2-phase regimen.\textsuperscript{105-108} Growth-modifying effects in some studies did not show an influence on the Class II skeletal pattern,\textsuperscript{107,109,110} while other studies dispute these findings.\textsuperscript{111,112} There is substantial variation in treatment response to growth modification treatments (headgear or functional appliance) and no reliable predictors for favorable growth response have been found.\textsuperscript{105,111} Some reports state early treatment does not reduce the need for either premolar extractions or orthognathic surgery,\textsuperscript{106,107} while others disagree with these findings.\textsuperscript{113} Two-phase treatment results in significantly longer treatment time.\textsuperscript{101,106,114}

Clinicians may decide to provide early treatment based on other factors.\textsuperscript{106,111} Preliminary evidence suggests that, for some children, early Class II treatment improves self-esteem and decreases negative social experiences.\textsuperscript{115} Incisor injury that is more severe than simple enamel fractures has been associ-
ated positively with increased overjet and prognathic position of the maxilla.116 Some studies indicate early treatment for Class II malocclusions can be initiated, depending upon patient cooperation and management.117

Treatment considerations: Factors to consider when planning orthodontic intervention for Class II malocclusion are: (1) facial growth pattern; (2) amount of AP discrepancy; (3) patient age; (4) projected patient compliance; (5) space analysis; (6) anchorage requirements; and (7) patient and parent desires. Treatment modalities include: (1) extraoral appliances (headgear); (2) functional appliances; (3) fixed appliances; (4) tooth extraction and interarch elastics; and (5) orthodontics with orthognathic surgery.102

Objectives: Treatment of a developing Class II malocclusion should result in an improved overbite, overjet, and intercuspation of posterior teeth and an esthetic appearance and profile compatible with the patient’s skeletal morphology.

Class III malocclusion

General considerations and principles of management: Class III malocclusion (mesocclusion) may be unilateral or bilateral and involves a mesial relationship of the mandible to the maxilla or mandibular teeth to maxillary teeth. This relationship may result from dental factors (malposition of the teeth in the arches), skeletal factors (asymmetry, mandibular prognathism, and/or maxillary retrognathism), or a combination of these factors.118

The etiology of Class III malocclusions can be hereditary, environmental, or both. In a study of 320 orthodontic patients in 155 sibships, the hereditary effect on molar relationship was determined to be 56%.119 Hereditary factors include clefts of the alveolus and palate and other craniofacial anomalies that are part of a genetic syndrome. Some environmental factors are trauma, oral/digital habits, caries, and early childhood OSAS.120

Treatment considerations: Treatment of Class III malocclusions is indicated to provide psychosocial benefits for the child patient by reducing or eliminating facial disfigurement and to reduce the severity of malocclusion by promoting compensating growth. Early Class III treatment has been proposed for several years and has been advocated as a necessary tool in contemporary orthodontics.121-126 Factors to consider when planning orthodontic intervention for Class III malocclusion are: (1) facial growth pattern; (2) amount of AP discrepancy; (3) patient age; (4) projected patient compliance; (5) space analysis; (6) anchorage (headgear); (7) functional appliances; (8) fixed appliances; (9) tooth extraction; (10) interarch elastics; and (11) orthodontics with orthognathic surgery.127

Objectives: Early Class III treatment may provide a more favorable environment for growth and may improve occlusion, function, and esthetics.128 Although early treatment can minimize the malocclusion and potentially eliminate future orthognathic surgery, this is not always possible. Typically, Class III patients tend to grow longer and more unpredictably and, therefore, surgery combined with orthodontics is the best alternative to achieve a satisfactory result for some patients.102

Treatment of a Class III malocclusion in a growing patient should result in improved overbite, overjet, and intercuspation of posterior teeth and an esthetic appearance and profile compatible with the patient’s skeletal morphology.
